SUMMARY

Recent genomic analyses of pathologically defined tumor types identify “within-a-tissue” disease subtypes. However, the extent to which genomic signatures are shared across tissues is still unclear. We performed an integrative analysis using five genome-wide platforms and one proteomic platform on 3,527 specimens from 12 cancer types, revealing a unified classification into 11 major subtypes. Five subtypes were nearly identical to their tissue-of-origin counterparts, but several distinct cancer types were found to converge into common subtypes. Lung squamous, head and neck, and a subset of bladder cancers coalesced into one subtype typified by TP53 alterations, TP63 amplifications, and high expression of immune and proliferation pathway genes. Of note, bladder cancers split into three pan-cancer subtypes. The multiplatform classification, while correlated with tissue-of-origin, provides independent information for predicting clinical outcomes. All data sets are available for data-mining from a unified resource to support further biological discoveries and insights into novel therapeutic strategies.

INTRODUCTION

Cancers are typically classified using pathologic criteria that rely heavily on the tissue site of origin. However, large-scale genomics projects are now producing detailed molecular characterizations of thousands of tumors, making a systematic molecular-based taxonomy of cancer possible. Indeed, The
Cancer Genome Atlas (TCGA) Research Network has reported integrated genome-wide studies of ten distinct malignancies: glioblastoma multiforme (GBM) (Cancer Genome Atlas Research Network, 2008), serous ovarian carcinoma (OV) (Cancer Genome Atlas Research Network, 2011), colon (COAD) and rectal (READ) adenocarcinomas (Cancer Genome Atlas Research Network, 2012b), lung squamous cell carcinoma (LUSC) (Cancer Genome Atlas Research Network, 2012a), breast cancer (BRCA) (Cancer Genome Atlas Research Network, 2012c), acute myelogenous leukemia (AML) (Cancer Genome Atlas Research Network, 2013b), endometrial cancer (UCEC) (Kandoth et al., 2013b), renal cell carcinoma (KIRC) (Cancer Genome Atlas Research Network, 2013a), and bladder urothelial adenocarcinoma (Cancer Genome Atlas Research Network, 2014). Those studies have shown that each single-tissue cancer type can be further divided into three to four molecular subtypes. The subclassification is based on recurrent genetic and epigenetic alterations that converge on common pathways (e.g., p53 and/or Rb checkpoint loss; RTK/RAS/MEK or RTK/PI3K/AKT activation). Meaningful differences in clinical behavior are often correlated with the single-tissue tumor types and, in a few cases, single-tissue subtype identification has led to therapies that target the driving subtype-specific molecular alteration(s). EGFR mutant lung adenocarcinomas and ERBB2-amplified breast cancer are two well-established examples.

To move toward a molecular taxonomy, we investigated whether tissue-of-origin categories split into subtypes based upon multiplatform genomic analyses and also extend the analysis in the other direction to look for possible convergence. We looked to see what molecular alterations are shared across cancers arising from different tissues and if previously recognized disease subtypes in fact span multiple tissues of origin. With those questions in mind, we performed a multiplatform integrative analysis of thousands of cancers from 12 tumor types in The Cancer Genome Atlas (TCGA) project. Using data from multiple assay platforms, we tested the hypothesis that molecular signatures provide a distinct taxonomy relative to the currently used tissue-of-origin-based classification. At the center of our results is the identification of 11 “integrated subtypes.” Consistent with the histological classification, tissue-of-origin features provided the dominant signal(s) for identification of most subtypes, irrespective of genomic analysis platform or combination thereof. However, approximately 10% of cases were reclassified by the molecular taxonomy, with the newly defined integrated subtypes providing a significant increase in the accuracy for the prediction of clinical outcomes.

RESULTS

Samples, Data Types, and Genomic Platforms
To identify a multitissue, molecular signature-based classification of cancer objectively, we first characterized each of the individual tumor types using six different “omic” platforms. The diverse tumor set called “Pan-Cancer-12,” is composed of 12 different malignancies. It comprises 3,527 cases assayed by at least four of the six possible data types routinely generated by TCGA: whole-exome DNA sequence (Illumina HiSeq and GAII), DNA copy-number variation (Affymetrix 6.0 microarrays), DNA methylation (Illumina 450,000-feature microarrays), genome-wide mRNA levels (Illumina mRNA-seq), microRNA levels (Illumina microRNA-seq), and protein levels for 131 proteins and/or phosphorylated proteins (Reverse Phase Protein Arrays; RPPA). The 12 tumor types include the ten TCGA Network published data sets listed above and two additional tumor types for which manuscripts have been submitted: lung adenocarcinoma (LUAD) and head and neck squamous cell carcinoma (HNSC). This is the most comprehensive and diverse collection of tumors analyzed by systematic genomic methods to date.

We performed sample-wise clustering to derive subtypes based on six different data types separately: DNA copy number, DNA methylation, mRNA expression, microRNA expression, protein expression, and somatic point mutation (see Extended Experimental Procedures, Section 1). The classification results from each single-platform analysis produced sets of 8 to 20 groups of samples that each showed high correlation with tissue of origin (Figures S1A–S1F available online) and were highly comparable with each other (Figure S2A). For example, patterns of copy-number change varied across tissue types, and subtyping of the tumors based on copy-number alterations revealed a significant correlation with tissue (p < 6x10⁻⁶, Chi-square test).

Integrated Platform Analysis—Cluster-of-Cluster Assignments
To identify disease subtypes on a more comprehensive basis than could be done using any single type of data, we developed an integrated subtype classification for all of the tumor samples in the Pan-Cancer-12 collection based on five of the data types, excluding somatic mutations. To do so, the results of the single-platform analyses were provided as input to a second-level cluster analysis using a method we refer to as cluster-of-cluster assignments (COCA), which was originally developed to define subclasses in the TCGA breast cancer cohort (Cancer Genome Atlas Research Network, 2012c). The algorithm takes as input the binary vectors that represent each of the platform-specific cluster groups and reclusters the samples according to those vectors (see Extended Experimental Procedures, Section 2). One advantage of the method is that data across platforms are combined without the need for normalization steps prior to clustering. In addition, each platform influences the final integrated result with weight proportional to the number of distinct subtypes reproducibly found by consensus clustering. Thus, “large” platforms (e.g., 450,000 DNA methylation probes) with orders of magnitude more features than “small” platforms (e.g., 131 RPPA antibodies) do not dominate the solution.

In addition to the COCA classification, we used two additional, independent methods to derive Pan-Cancer-12 subtypes based on integrated data: (1) an algorithm called SuperCluster (Kandoth et al., 2013b) (Figure S2B) and (2) clustering based on inferred pathway activities from PARADIGM (Vaske et al., 2010), which integrates gene expression and DNA copy-number data with a set of predefined pathways to infer the degree of activity of 17,365 pathway features such as proteins, complexes, and cellular processes (Figure S2C). Both SuperCluster and PARADIGM produced classifications that were highly concordant with the COCA subtypes (Figure S2D). Given recent promising results that use gene networks (as opposed to the sparsely
Grilley-Olson et al., 2013). That difficulty poses an important clinical challenge since histology is used to guide the selection of chemotherapy (Scagliotti et al., 2008) and to select patients for further mutational analysis (e.g., EGFR fusion testing in nonsquamous NSCLC). However, the challenge can be addressed by genomic analysis based on distinct differences in mutation spectrum (Table S2A) and distinct gene expression patterns (Figure S1A). Two clear subtypes of NSCLC (C1-LUAD-enriched and C2-squamous-like, see discussion below) are identified by COCA.

For the other five tissue types, the patterns are more complex. Either a given tissue splits into multiple COCA groups (divergence) or multiple tissue types coalesce into a single COCA group (convergence). A simple example of convergence previously described for TCGA data are the merging of colon (COAD) and rectal (READ) tumors into a single COCA group (Cancer Genome Atlas Research Network, 2012c), the findings here provide a more refined, quantitative picture of the extent of difference from luminal and basal-like breast cancers. Whereas tissue of origin is the dominant signal for combined data on almost all of the other cancer types in the Pan-Cancer-12 collection, breast basal-like cancers are as different from luminal/ER+ breast cancers as they are from cancers of the lung (Figure 1A). The data from the present study

The name of each COCA subtype (top row) includes a cluster number (1 to 13) and a text designation for mnemonic purposes. Two of the subtypes (numbers 11 and 12) were eliminated from further analysis because they included < 10 samples (3 and 6 samples, respectively). Hence, the text focuses on 11 subtypes, not 13.

See also Table S1.

Table 1. The 12 Pathological Disease Types, Rows, and Their Relationship to the 13 Integrated Subtypes Defined by the Cluster-of-Cluster Assignments Method
strongly reinforce the idea that basal-like breast cancers constitute a unique disease entity.

The remaining three tissue types (HNSC, LUSC, and BLCA) provide examples of both divergence and convergence in COCA subtyping (Figure 1A and Table 1). The strongest pattern of convergence is observed for the vast majority of HNSC (301/304), LUSC (206/238), and some of the BLCA (31/120) tumors; they cluster together in a large COCA group (C2-squamous-like), perhaps reflecting similar cell type of origin or smoking as an etiologic factor. BLCA tumors also exhibit a divergence pattern, distributing predominantly into three distinct groups: 31 BLCA in the C2-squamous-like group, 10 in the C1-LUAD-enriched group, and 74 in the bladder-only group, C8-BLCA. Five other BLCA samples cluster in four different COCA groups.

Clinical Importance of the COCA Subtypes
To investigate the clinical relevance of the COCA subtypes, we performed Kaplan-Meier Survival analysis on the Pan-Cancer-12 data set. The results indicate that tissue-of-origin (Figure S3A) and COCA subtype (Figure 1D) are both prognostic, and each provides independent information (Figure 1E). Additionally, the two most commonly mutated genes in the overall data set, TP53 (41%) and PIK3CA (20%), are prognostic, even across different tumor types, as are previously defined genomic signatures of cell proliferation rate (Nielsen et al., 2010) and mutated TP53 gene-expression-based signature (Troester et al., 2006) (Figures S3B–S3F).

We next asked whether prognostic information is provided by the COCA subtypes after accounting for known clinical and tissue-of-origin features. We performed a multivariate Cox proportional hazards analysis to predict outcomes across the data set. The analysis was limited to the COCA subtypes that did not have a one-to-one relationship with tissue-of-origin tumor type (COCA1-LUAD enriched, COCA2-squamous, COCA3-BRCA/luminal, COCA4-basal, COCA7-COAD/READ, and COCA8-BLCA). In the model we included clinical features such as tumor size, node status, metastasis status, and age at diagnosis, as well as tissue of origin. We performed a likelihood ratio test conditioning first on the clinical variables; when either tissue-of-origin or COCA subtype was added to the model, a large increase in the predictive fit of the model was observed, beyond what one would get with the clinical information alone (Figure 1E). That observation supports the classical model in which tissues of origin provides strong predictions of outcome. Next, we asked whether the COCA subtypes add additional independent information for predicting survival beyond the combination of tissue-of-origin and clinical features. Indeed, we observed a significant increase in statistical likelihood when COCA is added to a multivariate model that already includes the clinical and tissue-based information (p < 0.0002; Chi-square test; Figure 1E). Thus, while the COCA classification differs from tissue-of-origin-based classification in only ~10% of all samples, the difference does provide important molecular information that reflects tumor biology and is associated with clinical outcome.

Genomic Determinants of the Integrated COCA Subtypes
We next identified the major genomic determinants of the COCA subtypes, including somatic mutations and DNA copy-number changes (Figures 1B and 1C). For single-nucleotide variants, we analyzed a Pan-Cancer-12 list of 127 significantly mutated genes (SMGs) obtained by MuSiC analysis (Kandoth et al., 2013a). Only three of the genes are mutated at a frequency ≥10% (TP53, PIK3CA and PTEN), and 11 additional are mutated at ≥5% frequency (Table S2A). We also include a list of 291 high-confidence cancer drivers (HCDs) from Pan-Cancer-12 analysis (Tamborero et al., 2013) and identified by a combination of five complementary methods to identify signals of positive selection in the mutational pattern of genes across tumors.

A large number of correlations between COCA subtypes and somatic mutations were found (Figure 2A, Figure S4D, Data S2). Somatic mutations clearly distinguish the C1-LUAD-enriched group from the C2-squamous-like group. KEAP1 and STK11 are preferentially mutated in C1-LUAD-enriched tumors, whereas CDKN2A, NOTCH1, MLL2, and NFE2L2, among others, are preferentially mutated in C2-squamous-like (Figure 2A). A similarly distinct set of SMGs was seen for the C3-BRCA/luminal and C4-BRCA/basal groups; only two genes are shared (TP53 and PIK3CA), and they show different
mutation frequencies (Table S2A). Since the somatic mutation results were not used in any way to determine the COCA subtypes, they provide independent evidence that distinctly different genetic events underlie the subtypes. A protein-protein interaction network analysis of mutations associated with the COCA subtypes obtained using a new version of...
the HotNet algorithm (Vandin et al., 2012) provides an overview of the genomic determinants of the COCA subtypes (Figure S4 E).

The degree of genomic instability was a major determinant of subtype, as revealed in copy-number variation (CNV) data (Figure 2B). The C9-OV, C4-BRCA/basal, and C1-LUAD-enriched subtypes showed the most marked genomic instability, as assessed by average number of copy-number segments per subtype (Figure 2C), whereas AML and UCEC showed the least. Numerous COCA subtype-associated alterations implicated specific regions, arm-level copy-number changes (Figure S4 A) and/or focal regions of copy-number alteration (Figure S4 B). Of note were a number of previously described tissue-type-specific and subtype-specific alterations, including Chr7 gain and Chr10 loss in GBM (Cancer Genome Atlas Research Network, 2012b), 3p loss and 5q gain in kidney (Cancer Genome Atlas Research Network, 2012a), and 3p loss and 3q gain in lung squamous tumors (Cancer Genome Atlas Research Network, 2012a). Of note, the latter were seen in most C2-squamous-like tumors, regardless of tissue of origin.

Expression-Based Determinants of the Integrated Subtypes

We next sought to identify gene expression modules characteristic of each COCA subtype. First, we started with 6,898 sets of gene signatures documented to be coexpressed, coamplified, or to function together. From these, we identified gene programs as those whose genes have mRNA-seq signatures of high mutual correlation across the Pan-Cancer-12 data set. After applying a bimodality filter and weighted gene correlation network-based clustering, 22 nonredundant gene programs were identified (Table S4 A, Figure S5 A, Extended Experimental Procedures, Section 5, and Data S5). Linear classification with the 22 gene programs reconstituted the 11 integrated subtypes with 90% accuracy (Figure S5A and Table S4B). To view the expression-based determinants of the integrated subtypes, we plotted the average expression level of each gene program within each COCA cluster (Figure 3). As expected, the gene programs GP6-squamous differentiation/development, GP3-neural signaling, and GP20-TAL-1 leukemias/erythropoiesis were the most highly expressed in the C2-squamous-like, C10-GBM, and C13-LAML subtypes, respectively. As well, GP7-Estrogen signaling was highest in the C3-BRCA/luminal cases, whereas GP17-basal signaling had its highest levels in the C4-BRCA/basal cases. Activated pathway characteristics found by enrichment and subnetwork analyses based on PARADIGM infer-ences, many of which were consistent with the gene program analysis, are summarized in Table S4 A (see Extended Experimental Procedures).

Figure 3. Subtype-Specific Patterns of Gene-Program and Selected Pathway Expression Characterizing Each Pan-Cancer-12 COCA Subtype

The heat map shows integrative subtypes in numerical order. Gene programs (top) and pathway signatures from a compendium (Table S4) containing signatures for drug targets and canonical pathways (bottom) were clustered separately from each other. Red-blue intensities reflect the means of the scores (red = high, white = average, blue = low). See also Figures S5 and S6, and Data S5.
patient outcome in kidney cancer using a Cox proportional hazards survival analysis (Figure S5D and Table S4F). In common with the C3-BRCA/luminal subtype cases, higher levels of estrogen signaling (GP7) were also associated with better prognosis for C5-KIRC cancers. Consistent with the higher frequency of elevated HER2 protein levels in bladder, colorectal, and serous endometrial cancers (Akbani et al., 2014), the HER2-amplified gene signature appeared elevated in the C8-BLCA, C7-COAD/READ, and C6-UCEC subtypes, as well as the C3-BRCA/luminal subtype which contains all HER2-positive breast cancers. Predictors independent of disease stage included basal signaling (GP17), associated with decreased overall survival, and the immune-related PARADIGM pathways PD1_ signaling and CTLA4_pathway, both of which were associated with increased overall survival. These immune-related signatures may reflect varying amounts of lymphocyte infiltrate in the tumors as has been estimated by DNA methylation-based analysis of the Pan-Cancer-12 data set (Figure S5E). In any case, these immune cell-associated gene programs may be pertinent to emerging treatment strategies based on immune modulation. Overall, despite unequivocal clinical information and follow-up across the many different Pan-Cancer types, expression-based determinants of the integrated subtypes were sufficiently informative to identify pathway-based features of prognostic value that transcend tissue-of-origin cancer types.

Multiple-Platform Determinants of the Integrated Subtypes

To gain insight into the genetic and epigenetic determinants that characterize each of the COCA subtypes, we calculated differential gene scores derived from each of the separate six platforms (see Extended Experimental Procedures, Section 4) as well as PARADIGM pathway features. All differential activities were mapped to individual genes so that thematic pathways could be identified (see Data S2). Copy-number data were summarized at the gene level using GISTIC 2.0 and t tests for every region surrounding gene transcriptional start sites. Genes with differential mRNA expression were identified using a SAM analysis on the RSEM values. Genes with differentially expressed protein products were determined by running a t test on the 131 protein forms represented on the RPPA data. For mutations, a Fisher’s exact test on the frequency within a COCA subtype compared to outside the subtype was performed for all of a set of 291 high-confidence driver genes (Tamborero et al., 2013). Differentially expressed miRNAs for each COCA subtype were identified using a Wilcoxon rank-sum test based on the miRNA-Seq data. Genes were then identified as those predicted to be targeted by a differentially expressed miRNA that was also anticorrelated across the Pan-Cancer-12 data set.

Three approaches were used to summarize the unique features of the COCA subtypes. First, gene set enrichment analysis (GSEA) was run on the single-platform gene-based results and then clustered for visual inspection to elucidate distinctive pathways (Figure S6A). Second, a supervised Elastic Net approach was used to classify the COCA subtypes with 95% accuracy in cross-validation and the predictive features were collected (Figure S6B; Data S3). Third, “regulatory hubs” from PARADIGM with more than 15 downstream targets and found to be differentially activated within a COCA subtype relative to other subtypes were collected (Table SSA). All three approaches revealed that each platform detects different pathways and features with respect to both COCA subtypes and data platforms. The identified discriminating features of the COCA subtypes conform several expectations: (1) C3-BRCA/luminal was defined by protein and gene signatures for ER and GATA3 determined by the Elastic Net model as well as by PIK3CA-related signaling revealed by copy-number variation-based and mutation-based GSEA, (2) C5-KIRC was defined by multiple features of hypoxia found by mutation- and mRNA-Seq-based GSEA as well as predictive Elastic Net features, and (3) C7-COAD/READ was in part defined by APC mutations.

Convergence of the Squamous-like Subtype

A striking finding of the integrative subtype analysis was the coalescence of four distinct tumor types (LUSC, HNSC, some BLCA, and a very few LUAD) into the single C2-squamous-like subtype. We investigated the genomic- and pathway-based determinants of the subtype. The three main tumor types included shared loss of 3p and increased TP63, PIK3CA, and SOX2 gene copies within a characteristic 3q amplicon (Figure 4A). Those regions are well known in LUSC (Cancer Genome Atlas Research Network, 2012a) and HNSC (Bhattacharya et al., 2011; Walter et al., 2013), and the results here extend that observation to include a subgroup of BLCA cases. In addition, the C2-squamous-like subtype tends to show amplification of MYC and loss of CDKN2A, RB1, and TP53. TP53 mutation is frequent (72%), followed by a dramatic drop-off in mutation frequency to MLL2 (20%), PIK3CA (19%), CDKN2A (18%), NOTCH1 (16%), NFE2L2 (10%), and MALAT1 (6%), the only other genes mutated at ≥10% frequency (Table S2A). Of potential interest in the C2-squamous-like group, tumors without TP53 mutations show a higher density of PIK3CA mutations (Figure 1), consistent with recent evidence linking PI3K activation and wild-type TP53 inactivation in HNSC (Herzig et al., 2013). Putative driver analysis identified several genes (PIK3CA, MLL3, and KEAP1) frequently mutated in the C2-squamous-like group but also in other COCA subtypes (Figure 4B). Of these, FRG1B and CASP8 were found to be significantly more associated with HNSC by Fisher’s exact test. Putative driver analysis also revealed a number of genes with higher mutation frequencies in the C2-squamous-like subtype than in any other subtype: TP53, SYNE1, MLL2, CDKN2A, NOTCH1, NFE2L2, and EP300, among others (Figure 4C; Figure S7A).

An extension of the HotNet algorithm (Vandin et al., 2012) was run on all genes mutated in ≥2% of any one subtype in conjunction with the HINT physical protein-protein interaction network (Extended Experimental Procedures, Section 4; Table S3). HotNet identified four subnetworks of mutated genes characteristic of the C2-squamous-like subtype (Table S3B). The largest, most frequently mutated subnetwork (91.7% of C2-squamous-like samples) includes many well-known cancer genes and tumor suppressors, including TP53, CDKN2A, and PTEN. The second most mutated subnetwork (59.9%) consists of NFE2L2, CUL3, and KEAP1, CCNE1, FBXW7, and NOTCH1.
NFE2L2, CUL3, and KEAP1 are well-known regulators of oxidative stress. The third most mutated subnetwork (37.1% of squamous samples) includes the ASCOM complex (MLL2 and MLL3) and the putative ASCOM-interacting protein KDM6A. These proteins are involved in histone modifications that promote transcription. In addition, consistent with previous reports on collective motility in squamous cell carcinomas (Friedl and Gilmour, 2009), RAC and RHO signaling are also elevated in the C2-squamous-like subtype based on PARADIGM analysis (Table S4A and Figure S7B).

**Molecular Features Common to the Squamous, Breast Basal, and Ovarian Subtypes**

Past work highlighted transcriptional similarities between the breast basal-like subtype and LUSC (Chung et al., 2002), as well as breast basal-like and serous ovarian cancers (Cancer...
Figure 5. Comparison of Molecular Characteristics of C2-Squamous-like, C4-BRCA/Basal, and C9-OV Subtypes Reveals Differences in TP63 and TP53 Signaling

(A) Relative significance of TP63 network activation within the C2-squamous-like and C4-BRCA/basal subtypes. The network neighbors surrounding the TAp63γ and dNp63α tetramer complexes that show significant activation (or inactivation) within the C2-squamous-like and/or C4-BRCA/basal subtypes relative to all other cases were visualized using Cytoscape (Shannon et al., 2003). Node shape reflects relative significance in the one-versus-all comparison (square: more significant in C2-squamous-like, triangle: more significant in C4-BRCA/basal). Node color indicates relative activity (red: activated in C2 and C4, blue: inactivated in C2 and C4, purple: activated in C2 but inactivated in C4, white: activated or inactivated in only one subtype).

(B) Box plot of isoform-specific levels of TP63 and TP73 within three of the TP53-frequently mutated COCA subtypes (C2-squamous-like, C4-BRCA/basal, and C9-OV).

(C) CircleMap of PARADIGM-Shift differences associated with TP53 mutations within the C2, C4, and C9 COCA subtypes. Samples were ordered first by integrative subtype membership (innermost ring), then by TP53 mutation status (second ring), and finally by P-Shift (outer ring, indicating TP53 activity). The GISTIC score (indicating CNV), mRNA expression level, PARADIGM upstream and downstream activities are shown in the third, fourth, fifth and sixth rings, respectively. Red-blue color intensity reflects magnitude (red: positive, blue: negative). TP53-truncating mutants are highlighted (black outlined wedge), and the mean P-shift scores of the truncating mutants are shown. Negative P-Shift scores (outer ring blue) predict loss of function (LOF).

(legend continued on next page)
Genome Atlas Research Network, 2012c). We therefore asked if those subtypes share additional characteristics. The C9-OV (94%), C4-BRCA/basal (80%) and C2-squamous-like (72%) subtypes have the highest frequencies of TP53 mutation. All three show a very high frequency of copy-number changes (Figure 2C), and all are significantly enriched with amplifications of 3q26 and 8q24/cMYC and losses of chromosomes 4q, 5q, 8p, and 18q (Figure 2B). The COCA subtypes share features common to a pan-cancer cluster identified by a parallel analysis of the transcriptional profiles of these same tumors (Martinez et al., 2014), which was found to be associated with genomic loss of CDKN2A (p16ARF), increased numbers of DNA double-strand breaks, high expression of cyclin B1, and upregulation of proliferation genes.

Consistent with our previous TCGA report noting the similarities between breast basal-like and serous ovarian cancers (Cancer Genome Atlas Research Network, 2012c), the copy-number profiles of the integrative subtypes place the C4-BRCA/basal subtype closest to the C9-OV subtype (Figure S4C); both are also near a cluster tree branch that contains C2-squamous-like and C8-BLCA. All six of those subtypes show TP53 mutation and large-scale copy-number changes.

Pathway commonalities between the C4-BRCA/basal and C9-OV subtypes (Table S3B) largely recapitulate previous findings using PARADIGM analysis that both subtypes show activation of cMYC and FOXM1/proliferation signaling (Cancer Genome Atlas Research Network, 2012c). However, HIF1A signaling in those subtypes, despite previously being reported as high, appears less active in this pan-cancer context, probably due to the presence of other cancer types with clearly elevated HIF1A signaling (e.g., C5-KIRC). In terms of gene programs, C2-squamous-like tumors show high expression of the basal signaling gene program (GP17), at levels comparable with those in the C4-BRCA/basal tumors (Figure 3). In addition, both subtypes show upregulation of the proliferation/DNA synthesis gene program (GP1), as well as signatures of TP53 mutation, MYC targets/TERT, VEGF signaling, and activation of the PD1 and CTLA4 immune costimulatory pathways (Table S4A, Figure 3). Indeed, principal components analysis showed that C2-squamous-like and C4-BRCA/basal tumors are the most similar COCA subtypes with regard to gene program/drug pathway expression (Figure S5B).

In line with those findings, a systematic search for PARADIGM pathway commonalities between the C2-squamous-like and C4-BRCA/basal tumors through the definition of a “basalness score” (Cancer Genome Atlas Research Network, 2012c) reveals shared activation of proliferation- and immune-related pathways. TP63 network dysregulation is apparent in HNSC and LUSC (Figure S7C, Table S5), as found previously (Cancer Genome Atlas Research Network, 2012a; Walter et al., 2013). It has also been associated with normal basal stem/progenitor cell function in other organs (e.g., breast, urogenital tract) (Crum and McKeon, 2010). However, closer scrutiny of the network neighborhood surrounding the TAp63 g and dNp63a complexes reveals that TP63 activation is more significant in the C2-squamous-like tumors than it is in the C4-BRCA/basals, and it involves a larger number of TP63 network targets (Figure 5A). Indeed, TP63 expression levels, in particular expression of the oncogenic ΔNp63 isoform, are significantly higher in the C2-squamous-like subtype than in the C4-BRCA/basal tumors (Figure 5B). Notably, we did not see TP63 network activity or increased expression in the C9-OV subtype (Table S4A and Figure 6B).

High TP53 mutation rates characterize several tumor types including those represented by the COCA subtypes C4-BRCA/basal, C9-OV, and C2-squamous-like (Table S2A). Surprisingly, our pathway and gene program analysis reveal a pattern of TP53 compensation in the C2-squamous-like tumors that distinguishes them from these other subtypes with high TP53 mutation rates. First, the C2-squamous-like tumors do not exhibit significant loss of PARADIGM-inferred TP53 activity (Table S4A) and PARADIGM-SHIFT analysis (Ng et al., 2012) predicts loss-of-function of TP53-truncating mutations (observed in 43% of C4-BRCA/basal, 38% of C9-OV, and 30% of C2-squamous-like cases) at a significantly higher degree in the C4-BRCA/basal and C9-OV subtypes compared to the C2-squamous-like subtype (Figure 5C). Second, the copy-number data when aligned with TP53 missense and truncating mutations reveals more loss of heterozygosity (LOH) in the C9-OV and C4-BRCA/basal than in the C2-squamous-like samples. The apparent higher TP53-pathway activity in C2-squamous-like tumors may be related to the expression of isoforms of related family members TP63 and/or TP73 (Figure 5B), which may compensate for TP53 mutation in the C2-squamous-like tumors as revealed by PARADIGM-Shift analysis (Figure 5C), and as supported by functional experimental data in HNSC lines and tumors (Lu et al., 2011). In HNSC, the function of TP63/73 in growth of HNSC is modulated in the presence of inflammatory factor TNF-α and cREL. Third, the transcriptional targets of TP53 shared with TP63/73 appear to be more highly expressed in the C2-squamous-like subtype than in the C9-OV or C4-BRCA/ basal subtype (Figure 5D). Indeed, hierarchical clustering of 33 TP53-related gene signatures subsets the C2-squamous-like, C4-BRCA/basal and C9-OV tumors predominantly by subtype (left side dendrogram subtree: 99% C4-BRCA/basal/ C9-OV; right-side dendrogram subtree: 98% C2-squamous-like) (Figure 5D).

(D) Unsupervised clustering of C2-squamous-like, C4-BRCA/basal, and C9-OV cancers based on the expression patterns of 33 published TP53-related gene signatures. Sample subtype assignment (pink, C2-squamous-like, blue: C4-BRCA/basal; purple, C9-OV) and TP53 mutation status (wild-type, white; truncating, black; missense, gray) are indicated in the column color bar. Heatmap red-blue color intensity reflects magnitude (red, positive; white, average; blue, negative). Three main clusters of correlated signatures were identified (denoted I, II, and III); see Data S4 (syn2491513) for complete list of signatures in each cluster. See also Figure S7 and Table S5.
breast cancers (Leong et al., 2007). These studies show the potential for p63/73 compensatory function for mutated or suppressed p53 in HNSCC and breast cancer, which has potential implications for targeted and standard therapy across these malignancies. These data indicate that TP53/63/73 downstream activities are of potentially broader significance among the C2-squamous-like, C9-OV and C4-BRCA/basal subtypes, with similarly high TP53 mutation rates.

Figure 6. Divergence of the Bladder Cancer Samples across Multiple COCA Subtypes
(A) Kaplan-Meier survival analysis of bladder cancers within the C1-LUAD-enriched, C2-squamous-like, and C8-BLCA subtypes.
(B) Heatmap of 17 proteins expressed at significantly different levels within the C2-squamous-like relative to the C8-BLCA bladder cancer samples. Samples are arranged along the column by subtype (pink, C2; light blue, C8); and protein data are ordered along the rows by clustering. Rainbow color scale reflects magnitude (red, high; green, average; blue, low).
(C) HCD genes with differential mutation frequencies among the bladder samples clustered in COCA subtypes C1, C2, and C8. Differential frequencies reflect frequencies within, relative to frequencies outside of, the COCA subtype.
(D) Heatmap of 11 gene programs showing significant differential expression between the C2 and C8 bladder cancers. Samples are arranged along the column by subtype (pink, C2; light blue, C8), and gene programs are ordered along the rows by clustering. Red-blue color scale reflects magnitude (red, higher in C2; blue, higher in C8). Node size reflects relative significance, and node shape denotes feature type (diamond, multiprotein complex; v-shaped, cellular process; circle, genes; square, gene family). Color of an edge reflects type of interaction within the PARADIGM SuperPathway (purple arrows, activation; green T, inhibition).
See also Figure S8 and Table S6.
Divergence of Bladder Cancer Subtypes

Despite a relatively small sample size (n = 120), bladder cancer was one of the most diverse of the tumor types, with samples clustering into 7 of the 11 major COCA subtypes (Table S6). The majority of the samples fell into three main COCA groups: 10 in C1-LUAD-enriched, 31 in C2-squamous-like, and 74 in C8-BLCA. Correlation with histology showed that the bladder samples in the C2-squamous-like group did, indeed, have evidence of squamous features, although most in that subtype had less than 50% squamous differentiation upon review by a team of five urological pathologists. The genomic classifications are consistent with evidence for diverse squamous, adenocarcinoma and other variant histologies in bladder carcinoma (Willis et al., 2013). Because it is one of the most diverse tissue-of-origin tumor types in the Pan-Cancer-12 set, we looked at survival differences among the three main COCA groups of bladder cancers. Samples in the C2-squamous-like and C1-LUAD-enriched groups showed significantly worse overall survival than those in the C8-BLCA group (Figure 6A; Figure S8B). The same distinction held in proteomics-only analyses (Akbani et al., 2014), consistent with the worse overall survival of the other tumor types (LUAD, LUSC, and HNSC) that predominate in the C1-LUAD-enriched and C2-squamous-like subtypes.

We focused on the two larger subsets (C2-squamous-like and C8-BLCA) of bladder cancers, performing single-platform and integrated-platform comparisons. There are significant differences in copy number (Figure S4A), protein expression (Figure 6B), mutations (Figure 6C), gene programs (Figure 6D), and PARADIGM pathway networks (Figure 6E; Figure S8A). There is also a significant difference in 3p arm-level events; the C2-squamous-like subset shows the characteristic squamous-like pattern of 3p loss, whereas the C8-BLCA subtype does not (Figure 2B). Consistent with findings from the Pan-Cancer proteomics analysis (Akbani et al., 2014), higher HER2 and Rab25 protein levels are observed in the majority of the C8-BLCA cases relative to the C2-squamous-like bladder cases (Figure 6B). Conversely, markers of epithelial-to-mesenchymal transition (EMT) such as low E-cadherin, high fibronectin, and high N-cadherin expression are apparent in the C2-squamous-like bladder cancers (Figure 6B). Both gene program and PARADIGM analyses reveal differences in immune cell signatures; the bladder C2-squamous-like samples show higher levels of immune cell-associated signatures (Figure 6D and 6E). That difference, which has also been noted for lung squamous (Cancer Genome Atlas Research Network, 2012a) and breast basal-like cancers (Prat et al., 2010), could contribute to differences in outcome and suggest therapeutic targets.

DISCUSSION

This integrated multiplatform analysis of 12 cancer types provides independent and clinically relevant prognostic information above and beyond tumor stage and primary tissue-of-origin. Based on this study, one in ten cancer patients would be classified differently by this new molecular taxonomy versus our current tissue-of-origin tumor classification system. With respect to its therapeutic relevance, this proportion of potentially misclassified tumors is comparable to the rate of EGFR mutations in unselected non-small cell lung cancers (Lynch et al., 2004; Paez et al., 2004) and ERBB2 amplifications among all breast cancers (Cancer Genome Atlas Research Network, 2012c). If used to guide therapeutic decisions, this reclassification would affect a significant number of patients to be considered for nonstandard treatment regimens. In addition to identifying several new genomic and pathway insights between and within tissue-of-origin tumor types, this TCGA study provides a public resource compendium of individual and integrated data sets from six different “omic” platforms, comprehensively characterizing >3,500 tumors and enabling researchers to explore new questions and analytical approaches that will perpetuate this discovery process.

It is possible that each COCA subtype reflects tumors arising from distinct cell types. In this new taxonomy, cancers of nonepithelial origin (e.g., neural, muscle, connective tissue) appear most different from epithelial tumors based on virtually all molecular platforms. The next most marked difference is apparent between epithelial cancers arising from basal layer-like cells (C2-squamous-like and C4-BRCA/basal) and those with secretory functions (C1-LUAD-enriched and C3-BRCA/Luminal). Molecular commonalities within a COCA subtype suggest common oncogenic pathways. The C2-squamous-like cancers likely arise from a cellular subtype shared between environmentally exposed epithelial surfaces (e.g., oral cavity, lungs, and bladder); and malignancies from this cellular subtype possess a characteristic set of dysregulated genomic features, including SOX2 and ΔNp63 high expression (by 3q26-29 amplification) with TP53 mutation. Although some of these pathway features have previously been reported for normal squamous tissue development and homeostasis (Crum and McKeon, 2010) and in squamous cell carcinomas of specific organ sites (Maier et al., 2011; Yang et al., 2011), they have not previously emerged collectively as a broad subtype-defining phenotype from an integrated genomic analysis of thousands of different tumors. Cancers in the C2-squamous-like subtype appear most similar to those in the C4-BRCA/basal subtype, which in turn show pathway similarities to those in the C9-ovarian. While all three COCA subtypes exhibit comparably high TP53 mutation frequencies and expression of the GP17_Basal signaling gene program, the C2-squamous-like cancers are distinguished from all others by their significantly higher TP63 and TP73 expression, both short (ΔNp63, ΔNp73) and long (TAp63, TAp73) isoforms, which may partially compensate TP53 mutation in this COCA subtype.

In this integrated analysis, bladder cancers (BLCA) emerged as the most heterogeneous of all Pan-Cancer-12 malignancies, with multiple samples falling into primarily three different integrated subtypes (C1-LUAD-enriched-like, C2-squamous-like and C8-BLCA). The clinical relevance of Pan-Cancer integrated subtyping is apparent in this divergent cohort of tumors. Survival is dependent on subtype membership, with the C2-squamous-like BLCA cases showing earlier mortality than the more common C8-BLCA cases (Figure 6A). Those BLCA cases in the C2-squamous-like subtype display immune features common to the C2-squamous-like subtype, that are pertinent to two areas of current interest among bladder cancer researchers: (1) epidemiologic and experimental evidence that
chronic cystitis and recurrent bladder inflections (or other physical irritants) capable of inducing squamous metaplasia can predispose to squamous cancer of the bladder; and (2) the observation that early-stage bladder cancers are often responsive to intravesical T cell induction by Bacillus-Calmette-Guerin (BCG) anti-TB vaccination. These findings strongly support a COCA subtype specific approach to postsection surveillance, adjuvant therapy and management of metastatic disease for bladder cancer patients.

Our results suggest that “cell-of-origin” rather than pathway-based features dominate the molecular taxonomy of diverse tumor types. There are several possible explanations for this observation. First and foremost, there are hundreds to thousands of features (mRNAs, proteins, microRNAs) with cell-type specific expression patterns, whereas pathways tend to regulate a much smaller subset of components—tens to hundreds of genes and their products. Second, pathways are often used in a cell-type-specific manner (e.g., APC-pathway in colon/rectum); therefore, pathway-based features are likely subsumed by a cell-of-origin-based classification. Further research is needed to uncover pathway dependencies within a cell-of-origin context, of which many such relationships already exist (i.e., EGFR in LUAD, BRAF in Melanoma, etc.).

In closing, the refined molecular taxonomy we describe builds on centuries of pathology and genetic research. The data sets and results have been collected into a unified resource on Synapse to support integrative bioinformatics analysis. To support navigation through these findings, the results have been made available through several portals including the UCSC Genome Browser, Gitools, and MD Anderson’s Next Generation Heatmaps (see the Extended Experimental Procedures). New methods to mine these data will enable “subtracting away” the dominant cell-of-origin signals to reveal information about pathway signaling and tumor microenvironments (e.g., stromal and immune components). This new taxonomy provides independent prognostic information above and beyond stage and tissue of origin, and further investigations may provide novel pathway-based insights with clues for personalizing therapy. Follow-up studies are needed to validate the findings reported here, and additional samples and tumor types will extend the integrated analysis. However, this initial PanCancer-12 analysis lays the groundwork for a richer classification of tumors into molecularly defined subtypes unlike all prior cancer classification systems.

**EXPERIMENTAL PROCEDURES**

Data for the complete set of 5,074 TCGA samples were obtained for the December 22, 2012 Pan-Cancer-12 data freeze from the Sage Bionetworks repository, Synapse. All data are made available through the Synapse website (https://www.synapse.org) and referenced with Synapse identifiers denoted as synN, where N provides a unique identifier within the Synapse system. All result files relevant for subtyping and downstream analyses are available from syn2488297.

**Mutation Data and Predicted Driver Genes**

Single-nucleotide variant calls for all samples in each of the 12 different tumor types were obtained from the official data freeze for each individual data type. Briefly, mutation calls were obtained from the separate TCGA working groups and processed to de-duplicate and re-annotate them using the ENSEMBLE version 69 transcript database. The combined mutation annotation format (MAF) file is available from the Synapse resource.

One hundred and twenty-seven significantly mutated genes (SMGs) were identified in the entire sample set as those mutated more frequently than the background model according to MuSiC analysis as described in (Kandoth et al., 2013a). The SMG analysis was also performed by running MuSiC restricted to each COCA subtype. Lastly, genes whose mutations predominately occur within a given COCA subtype were identified by using the list of high-confidence drivers retrieved by the combined analysis of several signals of positive selection, as described in (Tamorero et al., 2013)

**Cluster-of-Cluster Assignments**

Subtypes derived from each of the six platforms—mRNA-Seq, miRNA-Seq, reverse-phase protein arrays (RPPA), structural copy-number alterations (SCNA), DNA methylation, and somatic mutations—were calculated as described in the Extended Experimental Procedures section. Subtype calls for each of the six platforms were used to identify relationships among the different COCA subtypes and coded into a series of indicator variables for each subtype. The binary matrix was then used in the ConsensusClusterPlus R-package (Wilkinson and Hayes, 2013) to identify patterns of relationship among the samples. ConsensusClusterPlus was run with 80% sample resampling and 1,000 iterations of hierarchical clustering based on a Pearson correlation distance metric. More information on integrative subtyping analysis can be found in Extended Experimental Procedures, Section 2. The integrated COCA subtypes are available on the Synapse resource.

**Survival Analysis for Pan-Cancer-12 and Squamous Bladder Samples**

Overall survival was calculated for samples using information from the enrollment and follow-up forms available at the DCC and downloaded on June 17, 2013. Kaplan-Meier survival plots were generated with the package Survival in R. A log-rank test was used to assess significance.

**SUPPLEMENTAL INFORMATION**

Supplemental Information includes Extended Experimental Procedures, eight figures, seven tables, and five data files and can be found with this article online at http://dx.doi.org/10.1016/j.cell.2014.06.049.

**CONSORTIA**
